Comparison with SQL

Since many potential pandas users have some familiarity with SQL, this page is meant to provide some examples of how various SQL operations would be performed using pandas.

If you're new to pandas, you might want to first read through 10 Minutes to pandas to familiarize yourself with the library.

As is customary, we import pandas and numpy as follows:

```
In [1]: import pandas as pd
In [2]: import numpy as np
```

Most of the examples will utilize the tips dataset found within pandas tests. We'll read the data into a DataFrame called *tips* and assume we have a database table of the same name and structure.

```
In [3]: url = 'https://raw.github.com/pandas-dev/pandas/master/pandas/tests/data
In [4]: tips = pd.read csv(url)
In [5]: tips.head()
Out[5]:
  total bill
               tip
                       sex smoker
                                   day
                                          time
                                                size
       16.99
              1.01
                    Female
                                   Sun
                                        Dinner
0
                               No
       10.34
              1.66
                      Male
                               No
                                   Sun
                                        Dinner
       21.01 3.50
                      Male
                                   Sun Dinner
                               No
       23.68 3.31
                      Male
                               No
                                   Sun Dinner
       24.59 3.61 Female
                                   Sun Dinner
                               No
```

SELECT

In SQL, selection is done using a comma-separated list of columns you'd like to select (or a * to select all columns):

```
SELECT total_bill, tip, smoker, time
FROM tips
LIMIT 5;
```

With pandas, column selection is done by passing a list of column names to your DataFrame:

```
In [6]: tips[['total bill', 'tip', 'smoker', 'time']].head(5)
Out[6]:
   total bill
               tip smoker
                             time
        16.99
              1.01
                       No Dinner
0
       10.34 1.66
                       No Dinner
2
       21.01 3.50
                       No Dinner
3
       23.68 3.31
                       No Dinner
4
       24.59 3.61
                           Dinner
                       No
```

Calling the DataFrame without the list of column names would display all columns (akin to SQL's *).

WHERE

Filtering in SQL is done via a WHERE clause.

```
SELECT *
```

```
FROM tips
WHERE time = 'Dinner'
LIMIT 5;
```

DataFrames can be filtered in multiple ways; the most intuitive of which is using boolean indexing.

```
In [7]: tips[tips['time'] == 'Dinner'].head(5)
Out[7]:
  total bill
               tip
                       sex smoker
                                   day
                                          time
                                                size
        16.99
              1.01
                    Female
                                   Sun Dinner
                               No
0
              1.66
       10.34
                      Male
                               No
                                   Sun Dinner
2
       21.01
              3.50
                      Male
                               No
                                   Sun Dinner
3
       23.68 3.31
                      Male
                                   Sun Dinner
                               No
4
       24.59 3.61
                    Female
                               No
                                   Sun Dinner
                                                   4
```

The above statement is simply passing a Series of True/False objects to the DataFrame, returning all rows with True.

```
In [8]: is_dinner = tips['time'] == 'Dinner'
```

```
In [9]: is dinner.value counts()
Out[9]:
True
         176
False
          68
Name: time, dtype: int64
In [10]: tips[is dinner].head(5)
Out[10]:
   total bill
               tip
                       sex smoker
                                          time
                                                size
                                   day
        16.99
              1.01
                    Female
                               No
                                   Sun Dinner
0
1
        10.34 1.66
                      Male
                               No Sun Dinner
2
       21.01 3.50
                               No Sun Dinner
                      Male
3
        23.68 3.31
                      Male
                                   Sun Dinner
                               No
                    Female
                               No
4
        24.59 3.61
                                   Sun
                                       Dinner
                                                   4
```

Just like SQL's OR and AND, multiple conditions can be passed to a DataFrame using | (OR) and & (AND).

```
-- tips of more than $5.00 at Dinner meals

SELECT *

FROM tips
WHERE time = 'Dinner' AND tip > 5.00;
```

```
# tips of more than $5.00 at Dinner meals
In [11]: tips[(tips['time'] == 'Dinner') & (tips['tip'] > 5.00)]
Out[11]:

                                         Sat Dinner
                                   Yes
```

NULL checking is done using the **notnull()** and **isnull()** methods.

```
In [14]: frame
Out[14]:
    coll col2
0     A     F
1     B     NaN
2     NaN     G
3     C     H
4     D     I
```

Assume we have a table of the same structure as our DataFrame above. We can see only the records where col2 IS NULL with the following query:

```
SELECT *
FROM frame
WHERE col2 IS NULL;
```

```
In [15]: frame[frame['col2'].isnull()]
Out[15]:
   col1 col2
1   B NaN
```

Getting items where coll IS NOT NULL can be done with notnull().

```
SELECT *
FROM frame
WHERE coll IS NOT NULL;
```

GROUP BY

In pandas, SQL's GROUP BY operations are performed using the similarly named <code>groupby()</code> method. <code>groupby()</code> typically refers to a process where we'd like to split a dataset into groups, apply some function (typically aggregation), and then combine the groups together.

A common SQL operation would be getting the count of records in each group throughout

a dataset. For instance, a query getting us the number of tips left by sex:

```
SELECT sex, count(*)
FROM tips
GROUP BY sex;

/*
Female 87
Male 157
*/
```

The pandas equivalent would be:

```
In [17]: tips.groupby('sex').size()
Out[17]:
sex
Female 87
Male 157
dtype: int64
```

Notice that in the pandas code we used size() and not count(). This is because count()
applies the function to each column, returning the number of not null records within each.

```
In [18]: tips.groupby('sex').count()
Out[18]:
        total bill tip smoker day time
                                           size
sex
                             87
                                        87
Female
                     87
                                  87
                                              87
                    157
                            157
                                 157
                                       157
Male
               157
                                             157
```

Alternatively, we could have applied the count() method to an individual column:

```
In [19]: tips.groupby('sex')['total_bill'].count()
Out[19]:
sex
Female 87
Male 157
Name: total_bill, dtype: int64
```

Multiple functions can also be applied at once. For instance, say we'd like to see how tip amount differs by day of the week - agg() allows you to pass a dictionary to your grouped DataFrame, indicating which functions to apply to specific columns.

```
SELECT day, AVG(tip), COUNT(*)
```

```
FROM tips
GROUP BY day;

/*

Fri 2.734737 19

Sat 2.993103 87

Sun 3.255132 76

Thur 2.771452 62

*/
```

Grouping by more than one column is done by passing a list of columns to the groupby() method.

```
SELECT smoker, day, COUNT(*), AVG(tip)
FROM tips
```

```
GROUP BY smoker, day;
/*
smoker day
No
       Fri
                   2.812500
       Sat
                   3.102889
               45
       Sun
               57
                   3.167895
       Thur
                   2.673778
               45
       Fri
Yes
               15 2.714000
       Sat
               42 2.875476
       Sun
               19 3.516842
       Thur
                  3.030000
*/
```

```
In [21]: tips.groupby(['smoker', 'day']).agg({'tip': [np.size, np.mean]})
Out[21]:
              tip
             size
                       mean
smoker day
No
       Fri
              4.0
                   2.812500
       Sat

                  3.516842
       Sun
       Thur
             17.0
                   3.030000
```

JOIN

JOINs can be performed with <code>join()</code> or <code>merge()</code>. By default, <code>join()</code> will join the DataFrames on their indices. Each method has parameters allowing you to specify the type of join to perform (LEFT, RIGHT, INNER, FULL) or the columns to join on (column names or indices).

Assume we have two database tables of the same name and structure as our DataFrames.

Now let's go over the various types of JOINs.

INNER JOIN

```
SELECT *
FROM df1
INNER JOIN df2
ON df1.key = df2.key;
```

```
# merge performs an INNER JOIN by default
In [24]: pd.merge(df1, df2, on='key')
Out[24]:
   key value_x value_y
0   B -0.318214  0.543581
1   D  2.169960 -0.426067
2   D  2.169960  1.138079
```

merge() also offers parameters for cases when you'd like to join one DataFrame's column with another DataFrame's index.

```
In [25]: indexed_df2 = df2.set_index('key')
In [26]: pd.merge(df1, indexed_df2, left_on='key', right_index=True)
Out[26]:
   key value_x value_y
1 B -0.318214 0.543581
```

```
3 D 2.169960 -0.426067
3 D 2.169960 1.138079
```

LEFT OUTER JOIN

```
-- show all records from df1
SELECT *
FROM df1
LEFT OUTER JOIN df2
ON df1.key = df2.key;
```

RIGHT JOIN

```
-- show all records from df2

SELECT *
FROM df1
RIGHT OUTER JOIN df2
ON df1.key = df2.key;
```

```
# show all records from df2
In [28]: pd.merge(df1, df2, on='key', how='right')
Out[28]:
   key   value_x   value_y
0    B -0.318214   0.543581
1   D   2.169960   -0.426067
2   D   2.169960   1.138079
3   E    NaN   0.086073
```

FULL JOIN

pandas also allows for FULL JOINs, which display both sides of the dataset, whether or not

the joined columns find a match. As of writing, FULL JOINs are not supported in all RDBMS (MySQL).

```
-- show all records from both tables

SELECT *

FROM df1

FULL OUTER JOIN df2

ON df1.key = df2.key;
```

UNION

UNION ALL can be performed using concat().

SQL's UNION is similar to UNION ALL, however UNION will remove duplicate rows.

```
Los Angeles 5
*/
```

In pandas, you can use concat() in conjunction with drop_duplicates().

Pandas equivalents for some SQL analytic and aggregate functions

Top N rows with offset

```
-- MySQL
SELECT * FROM tips
ORDER BY tip DESC
LIMIT 10 OFFSET 5;
```

```
In [34]: tips.nlargest(10+5, columns='tip').tail(10)
Out[34]:
     total bill
                          sex smoker
                  tip
                                       day
